ABSTRACT

Treatment of coking wastewater simulated by phenol with coconut shell modified Shanxi coal and N-Ce-TiO$_2$. The SEM of modified char showed that the particles were smaller and rougher than Shanxi coal. But the specific surface area larger. The SEM of TiO$_2$: showed that the particles of N-Ce-TiO$_2$ was smaller than others, the particles of Ce-TiO$_2$ between two parties, and the conclusion is the same to the BET.NH$_3$-TPD showed that the N and Ce can made the adsorption performance improved. UV-VIS N and Ce reduced the band gap and made the catalytic performance enhanced of visible light, potency:300mg/L,char:4g/L, pH=1, the efficiency of modified char is 62.5 %; potency: 20 mg/L, N-Ce-TiO$_2$:4g/L, pH=2, the efficiency of N-Ce-TiO$_2$ is 69 %. The efficiency of co-processing is better than that of single treatment and the BOD/COD of phenol wastewater about 600mg/L was more than 0.3. The application experiment of simulated wastewater shows that modified char and N-Ce-TiO$_2$ can treat phenol wastewater more efficiently and improve biodegradability, to lay a foundation for subsequent treatment.

1. INTRODUCTION

Coking waste water is produced in the process of coal-to-char, coal-gas purification and coking product recovery. There are many kinds of organic matter, mainly in the form of phenol, p-cresol, o-xylene and their homologues [1-2]. Organic pollutants contained in coking waste water seriously inhibit the growth and normal metabolic activities of microorganisms, resulting in the degradation of their biodegradability. Thus, treatment is very difficult, making it often difficult to meet the national emission standards. How to treat coking waste water economically and effectively has always been a hot issue in environmental protection.

It is feasible to treat coking waste water by adsorption and photocatalysis studied by scholars at home and abroad. The adsorption method takes advantage of the developed pores property of the adsorbent to adsorb the pollutants. The activated carbon has good adsorption performance, but its yield is low and cost is high. The utilization of inferior coal char to adsorb pollutants can greatly reduce the treatment cost. The modified TiO$_2$ is characterized by high photocatalytic activity, low cost and no secondary pollution. The use of TiO$_2$ for photocatalysis can effectively degrade organic macromolecules into small molecules and finally oxidize them to water and CO$_2$. Yang Xiaoxia et al. use modified coal char to adsorb benzoic acid. The experimental result shows that there are certain functional groups in the coal char, and the specific surface area increases to 143 m$^2$/g after modification with ammonia water [3]. Karri studies the adsorptive property of coconut shell activated carbon to phenol solution, finding that with the increase of phenol concentration, the adsorption efficiency decreases. The treatment efficiency of 250 mg/L phenol-containing waste water is 64 %, and activated carbon is low in yield and high in cost [4]; S. C. Liu et al. use modified char as adsorbent to treat coking waste water in depth. The experiment result shows that 13 g of modified char for every 200 mL of waste water can reduce the mass concentration of COD in waste water from 93 mg/L to about 48 mg/L, which can meet the requirement of circulating water for COD index [5]. Y. Lara et al. catalyze 30 mg/L phenol-containing waste water with TiO$_2$ UV-light 40 % degradation for four hours [6]. Antonopoulou M et al. study the phenol-containing waste water catalyzed by non-metallic modified TiO$_2$ by sol-gel method, finding that grain size, adsorption capacity and band gap can all influence the photocatalytic activity [7]; TiO$_2$ has a wide band gap (EG=3.2 eV) and can only respond to UV-light with wavelength less than 387 nm. To improve the photocatalytic performance of TiO$_2$ in visible light, element doping is one of the effective methods. Transition metals (Ce, etc.) have 4f electrons, easily produce multi-electron configurations, and their oxides also have many crystal forms, strong adsorption selectivity, and good electronic conductivity and thermal stability [8]. The doping of N element can shift the excitation light wavelength of TiO$_2$ to the visible region, and can effectively suppress the increase of the particle size of TiO$_2$. The decrease of the particle size is also beneficial to the increase of photocatalytic activity [9].

A large number of previous studies have focused on UV-light catalyzed phenol-containing waste water and activated carbon as an adsorbent to adsorb phenol-containing waste water. The concentration of photocatalytic treatment is low and the adsorption can’t effectively improve the biodegradability and the cost of activated carbon is high and difficult to recover. Thus, there are many defects in the
treatment of coking waste water. In view of this, this study uses modified coal char and metal non-metal co-doped TiO₂ to treat phenol-containing waste water, reduces the cost of adsorption, and realizes visible light catalysis. This study first uses modified coal char to adsorb high-concentration waste water and then uses TiO₂ visible light photocatalysis. The two complement with each other, which can not only expand the concentration range of waste water treatment, but also effectively improve the biodegradability, laying a foundation for further application.

2. MATERIALS AND METHODS

2.1 Industrial analysis of coal and biomass

The coal and biomass used in the experiment are naturally dried and ground into fine powder, and made into pulverized coal and biomass powder through a 240 mesh sieve and placed in a dryer. Industrial analysis is conducted on coal according to national standard GB/T212-2001. At present, the characteristic analysis method of biomass refers to the determination method of coal. The results are shown in Table 1.

2.2 Preparation of TiO₂

A certain proportion of butyl phthalate is rapidly added to absolute ethyl alcohol under rapid stirring to produce light yellow transparent solution, and then a certain proportion of absolute ethyl alcohol glacial acetic acid and water (cerium nitrate solution, hexamethylenetetramine solution) is mixed into solution B. Slowly drop B into A and stir for 15 minutes after mixing thoroughly to form yellow sol. Pour the sol into a hydrothermal kettle and move to an oven for a certain time. Remove the supernatant and calcine in a muffle oven after being dried by microwave oven, and then grind.

2.3 Performance test of materials

2.3.1 Characterization

Morphology analysis: SEM; composition and phase analysis: X-ray diffraction (XRD); specific surface area and pore size distribution: nitrogen adsorption and desorption, BET; absorption spectrum: ultraviolet and visible absorption spectrum (UV-vis).

2.3.2 Test on adsorptive property of coal char

The effects of different factors on the adsorptive property of coal char are studied by adding 4 g/L coal char, 300 mg/L phenol concentration, pH=1, 100 mL phenol solution, and shaking for 150 times with a constant temperature water bath oscillator.

2.3.3 Photocatalytic performance test of TiO₂

The photocatalytic activity of the prepared TiO₂ is studied in a self-made reactor. Coking wastewater is simulated with phenol solution by using energy-saving lamp light source. 4-aminoantipyrine spectrophotometry is used to determine and COD is determined by oven method. The effect of different factors on the adsorptive property of coal char is studied by adding 4 g/L TiO₂, 20 mg/L phenol concentration, pH=2 and 100 mL phenol solution.

3. RESULTS AND DISCUSSION

3.1 Characterization result

3.1.1 Characterization result of coal char

1) BET analysis

</table>

The specific surface area, pore volume and adsorption capacity of coal char doped with biomass and Ce-N-TiO₂ are greatly increased. The specific surface area of coal char modified by coconut shell is the largest, which is nearly 3 times that of pure Shanxi coal char. Further, the addition of biomass can obviously improve the adsorptive property of coal char. Because more alkali metal is contained in the biomass and Ce-N-TiO₂ acts as a catalyst to promote coke formation in the coal gasification reaction [10]. At the same pyrolysis time, a higher coal gasification reaction rate will inevitably increase the amount of volatile matter precipitating from coal, and the pore structure of the coal char will be more abundant, thus increasing the specific surface area by 207.83 m²/g compared with ammonia water modification [11]. In addition, the increase of pore volume and adsorption capacity is beneficial to the improvement of adsorptive property [12].

2) SEM analysis

From Figure 1, it can be seen the unmodified Shanxi coke particles are large and obviously agglomerated, the surface is relatively smooth, and the specific surface area is relatively small. Coal char particles modified with biomass and TiO₂ are relatively small, most of which are spherical, with rough surface, good dispersion and well-developed pore structure, so that their specific surface area is increased.
3.1.2 Characterization result of TiO$_2$

1) XRD Analysis of different TiO$_2$

As can be seen from XRD, doped TiO$_2$ can be indexed by the anatase phase TiO$_2$, and the peak form of all diffraction peaks is sharp, which indicates that the prepared catalyst is crystalline complete anatase TiO$_2$. The diffraction patterns of doped TiO$_2$ and pure TiO$_2$ are basically the same and have no impurity peaks, indicating that the doping of Ce and N enters the crystal and doesn’t change the original crystal structure. In addition, the radius of Ce$^{3+}$ and Ce$^{4+}$ is obviously larger than that of Ti$^{4+}$. If they enter the TiO$_2$ crystal lattice, the cell parameter will change obviously and the diffraction peak will shift to a small angle. It is shown that doping of Ce and N hinders the aggregation of TiO$_2$ grains [12], which decreases the grain size and increases the specific surface area of Ce-TiO$_2$. Compared with pure TiO$_2$, the average particle size of doped TiO$_2$ is smaller, of which Ce-N-TiO$_2$ is the smallest, about 10.57 nm. Grain size is smaller, the larger the Fermi energy level, which leads to the improvement of oxidation ability.

As can be seen from XRD, doped TiO$_2$ can be indexed by the anatase phase TiO$_2$, and the peak form of all diffraction peaks is sharp, which indicates that the prepared catalyst is crystalline complete anatase TiO$_2$. The diffraction patterns of doped TiO$_2$ and pure TiO$_2$ are basically the same and have no impurity peaks, indicating that the doping of Ce and N enters the crystal and doesn’t change the original crystal structure. In addition, the radius of Ce$^{3+}$ and Ce$^{4+}$ is obviously larger than that of Ti$^{4+}$. If they enter the TiO$_2$ crystal lattice, the cell parameter will change obviously and the diffraction peak will shift to a small angle. It is shown that doping of Ce and N hinders the aggregation of TiO$_2$ grains [12], which decreases the grain size and increases the specific surface area of Ce-TiO$_2$. Compared with pure TiO$_2$, the average particle size of doped TiO$_2$ is smaller, of which Ce-N-TiO$_2$ is the smallest, about 10.57 nm. Grain size is smaller, the larger the Fermi energy level, which leads to the improvement of oxidation ability.

3) SEM analysis of different TiO$_2$

![Figure 1. SEM of different modified Coal chars](image)

![Figure 2. XRD of different TiO$_2$](image)

![Figure 3. SEM of different TiO$_2$](image)
property of TiO$_2$ after doping modification is better than that of pure TiO$_2$.

4) NH$_3$-TPD analysis of different TiO$_2$

![Figure 4. NH$_3$-TPD of different TiO$_2$](image)

As can be seen from Figure 4, the pure TiO$_2$ catalyst contains approximately 4 desorption peaks, whereas the Ce (1 %)-TiO$_2$, Ce (1 %)-N (14 %)-TiO$_2$ catalyst contains approximately 5 desorption peaks. The location where the peak type is most prominent is in the temperature range of 300-400 °C. It is the main acidic center where NH$_3$ desorbs from the three catalysts and belongs to the medium strong acid site [14]. Obviously, the acid strength of the three catalysts shows a tendency that Ce (1 %)-N (14 %)-TiO$_2$, Ce (1 %)-TiO$_2$ and pure TiO$_2$ catalysts decrease in turn, showing that the surface acid site of Ce (1 %)-TiO$_2$ catalyst is significantly increased by doping Ce, while the surface acid site of Ce (1 %)-N (14 %)-TiO$_2$ catalyst is further increased by doping N. Therefore, the doping of Ce and N elements may increase the surface acid site on the catalyst surface [15], making the catalyst have higher acidity and have stronger adsorption effect on NH$_3$. It is proved that co-doping of Ce and N can improve the adsorptive property of TiO$_2$.

5) UV-vis analysis of different TiO$_2$

![Figure 5. UV-VIS of different TiO$_2$](image)

From Figure 5 (a), it can be seen that the pure TiO$_2$ absorption spectrum in the UV-light region is wider, and the spectral absorption range of the modified Ce-N-TiO$_2$ catalyst is wider than that of the visible light, which indicates that the utilization rate of the Ce-N-TiO$_2$ catalyst is the highest. The practicality is stronger and photocatalytic performance is the best. Figure 5 (b) shows the band gap of the two materials calculated according to the Tauc method. The band gaps of pure TiO$_2$, Ce-TiO$_2$ and Ce-N-TiO$_2$ are 2.83 eV, 2.54 eV and 2.32 eV, respectively. The smaller the band gap is, the stronger the absorption capacity of visible light is. This conforms to the conclusion of the left figure. The band gap of pure titanium dioxide is supposed to be 3.2 eV according to previous research reports. The smaller values measured here may be due to the occurrence of surface scattering to improve the light trapping capability [16]. When doped with Ce, the f-f transition of Ce$^{3+}$ occurs under visible light, which results in red shift of Ce-TiO$_2$ absorption spectrum, improving the absorption of TiO$_2$ in the visible region and widening the absorption range of visible light [17]. On this basis, doping of N element can make the conduction band and valence band move to the low energy direction so that the lower photon energy can make carriers be excited and transit, making the catalyst further red shift to a wider range [18]. This indicates that doping of Ce and N synergistically improves the photocatalytic performance.

3.2 Adsorptive property of coal char

3.2.1 Influence of Coke making temperature on adsorption performance

Under the same conditions, Shanxi coal char has the highest efficiency, and the best coking temperature is 850 °C. With the increase of calcination temperature, the volatile content in coal sample gradually decreases, resulting in the increase of porous structure and increase of specific surface area of coal char. However, when the calcination temperature reaches 950 °C, the sintering phenomenon occurs in different degrees during the coking process, which hinders the increase of the specific surface area and inhibits the improvement of the adsorptive property of coal char.

![Table 6. Influence of Coke making temperature on adsorption performance](image)

3.2.2 Adsorptive property of biomass modified coal char

In char preparation by mixing coal sample in proportion of coal species: biomass = 3: 7, the effect of biomass addition on adsorptive property is studied under the conditions of 0.4g of coal char, 300 mg/L phenol concentration, 100 mL phenol solution and 220 r/min stirring rate.

It can be concluded that the adsorption effect of Shanxi coal + coconut shell is better than other coal chars because the volatile content of coconut shell is higher than that of other biomass seen from the industrial analysis of biomass, which
results in that the produced biomass char itself has a higher specific surface area. In addition, the ash content of coconut shell is relatively high and the catalyst component contained therein is also relatively high, which does good to volatilization and dispersion loss, and also contributes to the increase of the specific surface area.

3.3 Study on photocatalytic activity of TiO₂

3.3.1 Study on the properties of different TiO₂

It can be seen from Table 7 that the phenol removal rate of different TiO₂ is improved under the condition of illumination, which indicates that different TiO₂ can be excited into photocatalytic performance under visible light. The removal efficiency of Ce-TiO₂ and N-Ce-TiO₂ is higher than that of pure TiO₂, which indicates that Ce-TiO₂ and N-Ce-TiO₂ have good photocatalytic properties.

![Figure 6. Photocatalytic efficiency of different TiO₂](image)

Figure 6. Photocatalytic efficiency of different TiO₂

3.3.2 Doping amount of elements and screening of N sources

It can be seen from table 8 that under the same preparation conditions, the photocatalytic efficiency increases first and then decreases as the doping amount of Ce increases. When the doping content of Ce is 1 %, the removal efficiency of Ce-TiO₂ to phenol is the highest. The possible reason is that the introduction of Ce can make up photo-generated electrons, inhibit the recombination of photogenerated holes, and improve the photocatalytic efficiency. However, if the doping amount is too large, it may become the center of electron-hole recombination, and decrease the photocatalytic activity. This may be due to the fact that the thickness of the space layer generated by the excitation of TiO₂ decreases with increase of Ce, which results from the fact that the space charge potential of the separated electron-hole pair is too low (less than 0.2 V) [19]. Therefore, the optimum doping amount of Ce is 1 %.

Table 8. Doping amount of elements and screening of N sources

<table>

<td>11</td>
</tr>
</tbody>
</table>

The removal efficiency of phenol by co-doping modified TiO₂ with hexamethyl ammonium as nitrogen source is obviously higher than that by co-doping modified TiO₂ with urea. The possible reason is that hexamethyl ammonium is less volatile and can provide N atoms into TiO₂. However, urea, as a nitrogen source, is volatile under high temperature calcination conditions and can’t provide N atoms into the TiO₂ lattice. Hence, the photocatalytic activity is low.

Under the same preparation conditions, the efficiency of photocatalytic reaction increases with the increase of doping amount of N. The removal efficiency of phenol by N-Ce-TiO₂ is the highest when the doping amount of N is 14 %. However, when the doping amount of N is further increased, the efficiency gradually decreases, indicating the synergistic effect of N and Ce on the catalytic activity. This is due to the doping of Ce introduces 4f energy level into the band gap of TiO₂. The interaction with the N₂p doping level widens the band range of TiO₂ in using solar energy [20]. When the doping amount of N is 14 %, N atoms enter the titanium dioxide crystal lattice to replace O atoms, and the number of N atoms in the crystal lattice is optimum, and electron-hole recombination is not excessively formed, so the photocatalytic activity is highest. Therefore, the optimum doping amount of N in this experiment is 14 %.

3.3.3 Optimum hydrothermal temperature and time

From Table 9, it can be seen that under the present experimental conditions, as the hydrothermal time increases, the photocatalytic activity also increases because the particle crystallinity is better as the hydrothermal reaction time and the hydrothermal temperature increase. Thus, the catalyst will also have a higher specific surface area. After 24 hours, the efficiency is basically unchanged, so the hydrothermal time used in this experiment is 24 hours. When the hydrothermal temperature is 160 °C, the treatment efficiency of phenol is the highest, which may be due to the fact that too low temperature will affect the progress of the reaction and complete crystals can’t be obtained while too high temperatures tend to cause collapse of pores and aggregation of particles, which is not conducive to the formation of crystals.

3.3.4 Influence of O₃ auxiliary oxidant

As can be seen from Figure 7, the addition of O₃ can effectively improve the photocatalytic oxidation capability of Ce-N-TiO₂ and expand the concentration range of the treatable phenol of Ce-N-TiO₂. For phenol solution with concentration of 100 mg/L or less, the co-oxidation efficiency of O₃ and Ce-N-TiO₂ can reach more than 90 %. For 150 mg/L phenol solution, the oxidation efficiency can reach above 80 %.

![Figure 7. Influence of O₃](image)

A large amount of OH [21] can be produced by the interaction of O₃ and H₂O. O₃ is also a good electron acceptor, which can prevent the recombination of photo-generated electron-hole pair on the surface of TiO₂ and improve the photocatalytic activity of Ce-N-TiO₂.

After the addition of O₃, the biodegradability can be significantly improved, especially at low phenol concentrations. This indicates that O₃ not only can effectively remove phenol and reduce the content of phenol in waste water, but also significantly accelerate the reaction rate of photocatalytic degradation of phenol by O₃. At the same reaction time, more phenol is degraded into organic small molecules, so that biochemical property of phenol waste water is obviously improved.

3.4 Combination

3.4.1 Treatment efficiency of adsorption-photocatalysis combination

From Figure 8, it can be seen that the treatment effect of phenol waste water by adsorption-photocatalysis combination is obviously better than that of the two alone. With the increase of phenol concentration, the removal effect is more obvious. In addition, when the phenol concentration is high, the removal efficiency of the adsorption-photocatalysis combination is larger than the combined treatment efficiency of the two mainly because the concentration of the phenol is greatly reduced after the adsorption treatment to reach the concentration range of the photocatalytic treatment. In addition, compared with the combined treatment result of ozone/activated carbon in document [22], the addition amount of the adsorbent is reduced from 50 g/L to 4 g/L, which is more than 10 times, and the removal efficiency is also improved by 20 %. The combined process of adsorption/Ce-N-TiO₂/O₃ photocatalysis improves the biodegradability of phenol waste water with lower concentration (about 600 mg/L), and the BOD/COD value is increased to more than 0.3, basically meeting the requirements of conventional biochemical treatment. For the high-concentration phenol waste water, the biodegradability is obviously improving and the BOD/COD value is increased by about 0.15 compared with that before the combination. Under the same experimental conditions, the improvement degree is higher than 0.08 of ozone/activated carbon combined treatment in document [23].

![Figure 8. Comparison of Phenol removal efficiency of photocatalysis and adsorption](image)
subsequent biochemical treatment or simplify the biochemical treatment process.

4. CONCLUSION

(1) The specific surface area of Shanxi coal char modified by coconut shell is increased to be 350.83 m²/g, which is 216.06 m²/g higher than that before modification. When the dosage of 300 mg/L phenol-containing waste water with is 4 g/L, the efficiency is 62.5 %, 33.4 % higher than that before modification;

(2) The modified TiO₂, Ce-TiO₂ and N-Ce-TiO₂ prepared by hydrothermal assisted sol-gel method are both anatase, which have larger specific surface area and smaller band gap, higher activity and stronger practicability under visible light. The visible light catalytic efficiency of 20 mg/L phenol-containing waste water is 60.4 % and 69.2 %, respectively, which is nearly 3 times higher than that before modification.

(3) The addition of O₃ auxiliary oxidant can produce more hydroxyl radicals, promote the catalytic efficiency of visible light, increase the concentration and efficiency of waste water treated with TiO₂, and make the total efficiency greater than the sum of the two.

(4) Modified coal char with coconut shell and N-Ce-TiO₂ can be used to treat phenol-containing waste water with high concentration, which can make the treatment efficiency reach more than 80 %, improve the biodegradability to make the BOD/COD higher than 0.3, laying a foundation for the follow-up treatment.
